The utility of standardized or crude weight measures in modeling of postnatal growth trajectories: Are there differences?

Ann Von Holle, Kari North, Ran Tao, UNC, Chapel Hill, NC; Sheila Gahagan, UCSD, San Diego, CA

Introduction

- Postnatal growth trajectory characteristics play an important role in life course analyses, and one common analytic approach is to assess growth differences according to prenatal exposures.
- Z-scores are a frequent outcome choice when modeling weight growth trajectories. **Advantages** include sex- and age-independent measures free of dimension. **Disadvantage** is measure designed for cross-sectional use.
- Compared to crude measures of weight, the advantages of standardized measures, such as Z-scores, are unclear.

Aim

- Estimate group differences in postnatal weight change across three different outcomes and three models to assess precision, type I error and parameter estimate values via Monte Carlo simulations.

Samples

- Growth trajectory parameters for baseline exposure correspond to estimates for three samples: Italy, Portugal and Chile [1].

Method

- We generated fixed effects infant growth data with a Reed first order parametric model

Source: $y_{ij} = \beta_0 + \beta_1 \cdot \mathtt{t}_{ij} + \beta_2 \cdot \ln(\mathtt{t}_{ij}) + \frac{\beta_4}{\mathtt{t}_{ij}} + \beta_5 \cdot \exp_i + \beta_3 \cdot \mathtt{t}_{ij} \cdot \exp_i + e_{ij}$

- After simulating weight values (10,000 iterations) for four baseline weight and slope scenarios, we fit three models for each of the three outcomes and three samples:

- **Model 1**
  $m_{ij} = \beta_0 + \beta_1 \cdot \mathtt{t}_{ij} + \beta_2 \cdot \exp_i + \beta_3 \cdot \mathtt{t}_{ij} \cdot \exp_i + \epsilon_{ij}$
- **Model 2**
  $m_{ij} = \beta_0 + \beta_1 \cdot \mathtt{t}_{ij} + \beta_2 \cdot \exp_i + \beta_3 \cdot \mathtt{t}_{ij} \cdot \exp_i + \beta_4 \cdot \mathtt{t}_{ij}^2 + \epsilon_{ij}$
- **Model 3**
  $m_i = \beta_0 + \beta_1 \cdot \mathtt{m6}_i + \beta_2 \cdot \exp_i + \beta_3 \cdot \mathtt{m6}_i \cdot \exp_i + \epsilon_i$

Model Terms

y_{ij}	weight for person *i* and time *j*
t	age (months)
m_{ij}	weight, WHO Z-score based on simulated weight, or percentile for person *i* and time *j*
exp	a binary exposure factor
m6	a binary variable for time with 1=month 6 and 0=month 0
e_{ij}	error term with covariance following an autocorrelation structure, ρ=0.5 and σ=0.75

Results

Figure 1: Sample of simulated weight growth curves (n=10) with corresponding Z-score and percentile outcomes using Chilean growth parameters

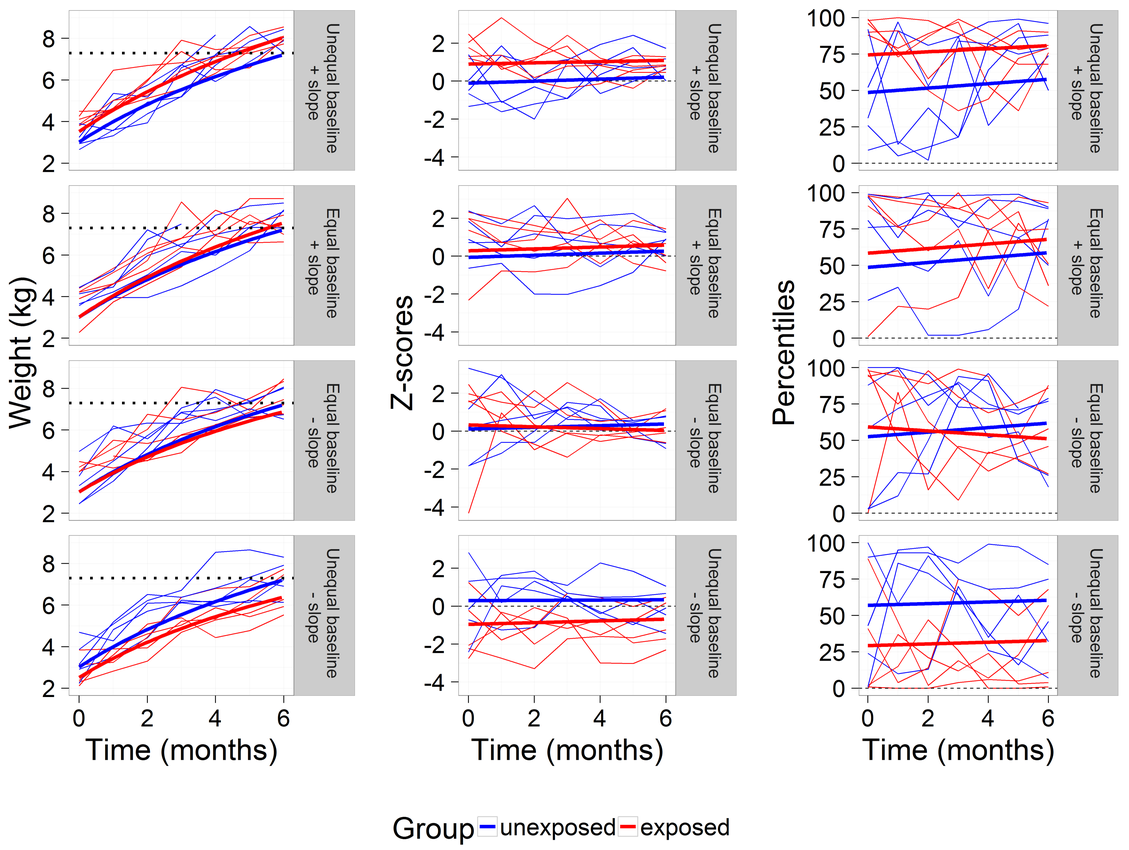

Figure 2: Comparison of power, type-I error and estimated product term for time and exposure effect, β_3.

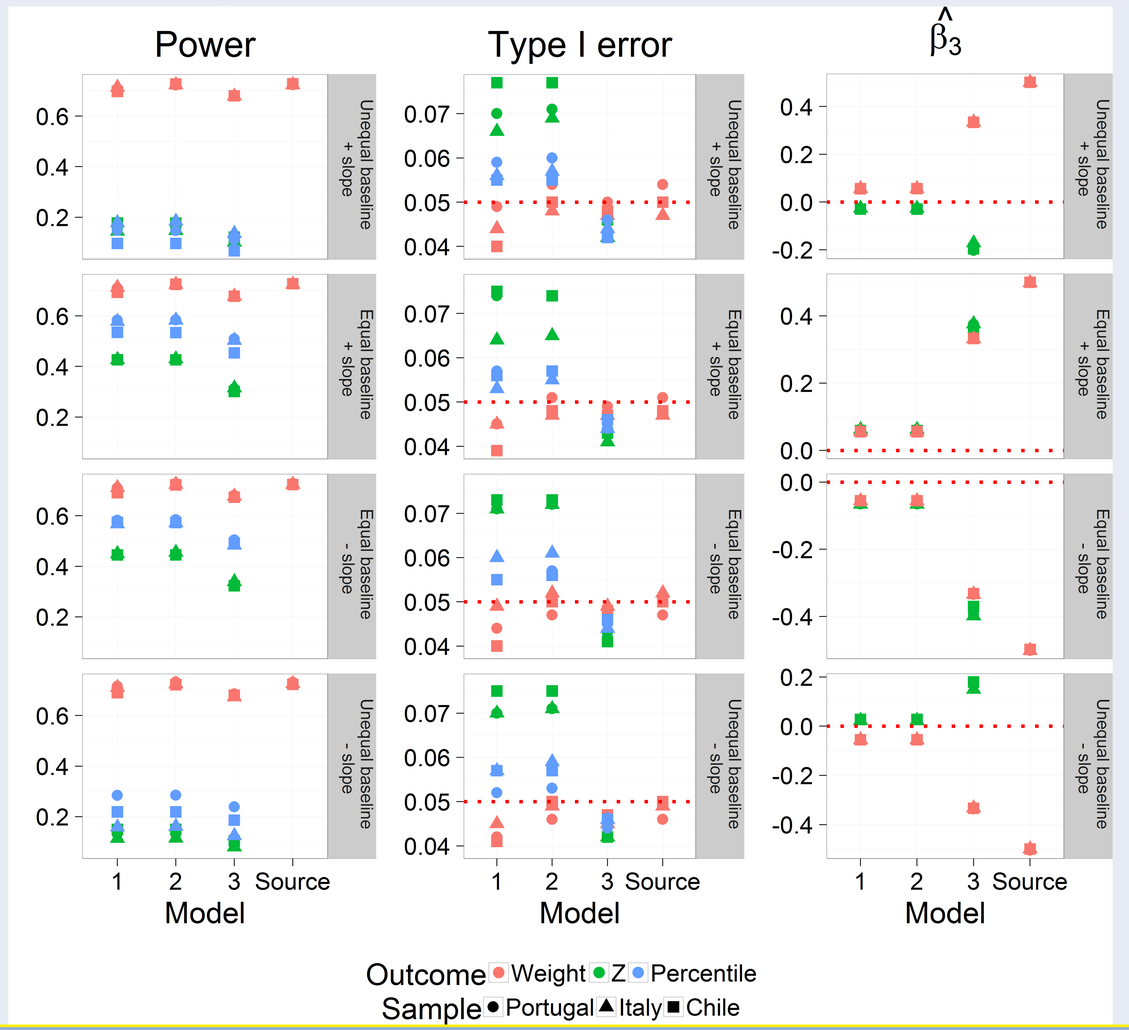

Results, cont . . .

Power: Consistently greater with crude weight.
- Weight difference at baseline results in larger differential between crude and standardized.

Type I error: Crude weight measure closest to nominal type I error of 0.05.
- Z-scores have greatest type I error for models 1 and 2.

Parameter estimates ($\hat{\beta}_3$): Baseline weight differences lead to opposite direction of effect, group difference in weight change over time, for Z-score compared to crude weight outcomes.
- No weight differences at baseline leads to similar estimates between Z-score and original weight outcomes.

Conclusions

Each measure examined in this project: Z-scores, percentiles and crude weight measures, serves a purpose. However, these outcomes in growth trajectory analyses are not equivalent and if used incorrrectly can have adverse effects.

- Even at similar age and gender values, estimated group differences in weight change over time are not similar for standardized and crude weight outcomes.
- Supporting this conclusion, estimated group differences in weight change for all three outcomes only coincide in direction under certain conditions – equivalent weight at baseline.
  ⇒ Special attention needed when interpreting standardized measures in longitudinal models, i.e. what is the appropriate target population?
- If comparisons to a standard are not an objective, using Z-scores instead of crude weight can lead to
  ⇒ biased estimates and conflicting inference
  ⇒ lower power and inflated type I error
- Findings replicate lower power for Z-scores found in adolescent age group [2].
- **Future efforts**: How does this discrepancy in parameter estimates extend to other contexts beside group comparisons in infant growth?
